ABSTRACT

Deviations in port container handling can be detected by many factors. One of them is anomalies in the process model. Several studies have proposed anomaly detection methods. However, these methods do not accommodate verbal judgments of experts. These methods treat instances with low deviation as containing anomalies while in reality not all instances with low deviation contain anomalies. Considering this, a method was developed for detecting anomalies in port container handling using fuzzy regression in order to accommodate verbal expert judgments on the rate of anomaly (ROA). First, a control flow pattern is built to form an anomaly pattern that will be used for detecting wrong patterns. Then, five anomaly attributes were declared, i.e. skip sequence, wrong throughput time (max), wrong throughput time (min), wrong patterns and wrong decisions. In the experiment, the rate of anomaly was found using three methods, namely fuzzy regression (FR), support vector regression (SVR) with radial basis function (RBF) kernel, and multiple linear regression (MLR). The results showed that fuzzy regression was better at detecting anomalies than multiple linear regression and support vector regression. The experimental validation showed that fuzzy regression combined with control flow pattern was able to reduce false positives and false negatives. The sensitivity, specificity and accuracy of the proposed method were 96%, 97% and 99%, respectively.

1. Introduction

Anomalies in a business process can be interpreted as processes or subprocesses that are not carried out as usual and are not in accordance with standard operation procedures (SOP) (Amara et al., 2013). If an accurate anomaly detection system and a properly functioning early warning system are implemented, several problems can be prevented, ranging from fraud to inefficiency. Recently, a case of extortion in port container handling in Samarinda, East Borneo was uncovered. It is assumed that this has caused a total loss of about 2 trillion rupiah or about 9% of annual revenue. It occurred without being detected from 2010 to 2016 (Rahmah).

Another example is, if work time deviations from standard operating procedures (SOPs) are identified timely, companies can change the pattern of work time intensity to minimize the possibility of transgressions.

Several studies have proposed anomaly detection methods however, they do not accommodate verbal expert judgments on the rate of anomaly (ROA). These methods treat instances with low deviation as anomalies, while in reality not all instances with low deviation are anomalies. Low deviation can be caused by ambiguity in determining the anomaly attribute values and low frequency of occurrence (Huda et al., 2016; Huda et al., 2015).

Here, we propose a method of detecting anomalies that accommodates verbal expert judgments on the rate of anomaly based on deviation from standard operating (SOP) procedures. SOP deviations are procedural errors that can cause anomalies. We propose the use of fuzzy regression and verbal expert judgments on the rate of anomaly to correctly detect fraudulent activities. We hypothesized that the weight of the anomaly attributes can affect the rate of anomaly. Finally, the anomaly rate is used to determine whether a deviation indicates high anomaly, medium anomaly, low anomaly or no anomaly. The major scientific contribution of this work is to reduce false positives and false negatives by improving the following indicators: skip sequence, skip decision, wrong throughput time (max), wrong throughput time (min), and wrong pattern.

A previous research (Correia, 2012) has proposed a standard business procedure with 43 variations of business process patterns from many fields called control flow patterns. In order to build an anomaly pattern model for detecting anomalies, especially wrong patterns, rules to build the anomaly patterns are needed. In this research, we built anomaly patterns and then used graph pattern matching to detect wrong patterns.

Graph isomorphism (Cordella et al., 2004; Nabti and Seba, 2016) is a method that can be added to graph pattern matching. It detects a subgraph model from a full graph model in the form of a business process model. The algorithm uses several graph matching rules, matching the degree of the nodes and the number of nodes and arcs. Here, we propose to build control flow patterns to detect wrong patterns by using graph isomorphism. However, the proposed graph isomorphism algorithm can only detect one of the anomaly attributes, i.e. wrong pattern. To detect the other 4 anomaly attributes, i.e. skip sequences, wrong throughput time (min), wrong throughput time (max), and wrong decision, detection rules are needed. Thus, this research declares rules for detecting 4 anomaly attributes.

In the proposed method anomalies are detected based on SOP deviations caused by skip sequence, wrong throughput time (min), wrong throughput time (max), wrong decision, and wrong pattern. The attribute values of the anomalies are discrete, i.e. high anomaly, medium anomaly, and low anomaly. Therefore, fuzzy regression is used to investigate the predicted anomaly rate (i.e. high anomaly, medium anomaly, and low anomaly) based on the attribute importance weights. We hypothesized that the importance weight of the attributes can provide the weight of attribute anomalies. Finally, the weight of the attribute anomalies can be used to determine whether an anomaly is high, medium, or low. The performance of fuzzy regression was compared with that of multiple linear regression and support vector regression with radial basis function (RBF) kernel to get the most accurate rate of anomaly predictions.

This research evaluated the accuracy of the proposed method in anomaly detection. This was done based on two aspects, i.e. sensitivity and specificity (Buijs et al., 2012).

The rest of this paper is structured as follows: Section 2 presents a literature review, Section 3 describes the proposed method for composing the control flow patterns and defining the anomaly attribute values, Section 4 reports the results and analysis of the experiment, Section 5 presents the conclusions of the research.

2. Material and methods

Rates of anomaly in port container handling in the form of discrete data were determined based on verbal expert judgments. Regression analysis is more appropriate for producing continuous output and not for discrete output as needed in the classification problem in this study. Some years ago regression-based classification has been introduced as an alternative method for dealing with classification problems. An interesting approach is classification based on support vector regression producing higher accuracy than multiple linear and non-linear regression. Regression-based classification has been successfully applied in face recognition (Liu et al., 2013) and data streaming (Osojnik et al., 2017) in real cases. However, while regression algorithms have widely been applied, problems may arise in some circumstances (Shapiro, 2005):

- Uncertainty between input and output variables (Chandola et al., Jul. 2009)
- Inadequate number of observations (Saia et al., 2017)
- Difficulty in verifying distribution assumptions (Mahapatra and Chandola, 1804)
- Ambiguity of incidence or extent of occurrence (Saia, 2017)
- Inaccuracies and distortions introduced by linearization (Akoglu et al., 2013)

From the description above, statistical regression is problematic. In this study, a fuzzy regression method was therefore developed to detect anomalies, accommodating verbal expert judgments on the rate of anomaly. Several regression techniques were evaluated to determine the regression model. The regression output was decoded corresponding to the class label (high anomaly, medium anomaly and low anomaly). Three regression methods, MLR, SVR RBF kernel and fuzzy regression (FR) were compared to get the most accurate rate of anomaly prediction. The details of the regression methods are given below.

2.1. Multiple linear regression

Algorithms to model the relationship between two or more independent and dependent variables or responses operate by applying a linear equation to the observed data. Each value of the independent variable x is related to a value of the dependent variable y (DeForest et al., 2017). In the present case of detecting anomalies in port container handling, multivariate data of attribute anomalies were used to predict the ROA. In an experiment, the ROA values (yi) were predicted by five predictors (x1, x2, ..., x5) as expressed by the equation as shown in Eq. (1).

\[ y_i = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_4 x_4 + \beta_5 x_5 \]  

where \( \beta_1 - \beta_5 \) are independent variables; \( \alpha \) is an independent variable; and variables \( x_1 \) to \( x_5 \) explain the anomaly attributes as shown in Table 1. Variable \( x_1 \) designates skip sequences, variable \( x_2 \) designates wrong decision, variable \( x_3 \) designates wrong pattern, variable \( x_4 \) designates wrong throughput time (min), variable \( x_5 \) designates wrong throughput time (max) and variable \( y_i \) designates the rate of anomaly.

The data used in the experiment described a total of 65,000 instances in 4 months. An expert in port container handling divided the data into 4 classes, namely High Anomaly, Medium Anomaly, Low Anomaly and No Anomaly. Also, the expert specified the following thresholds: below 0.6 means No Anomaly, between 0.6 and 0.7 means Low Anomaly, between 0.7 and 0.8 means Medium Anomaly, and between 0.8 and 1 means High Anomaly. With these thresholds, we found 680 instances containing anomalies and 64,320 instances not containing anomalies. The 680 instances with anomalies were used as training and testing data: 60% of the total anomaly instances were used as training data and 40% were used as testing data, as shown in Table 3. On average, there were 5 instances with anomalies every day (Table 4).

The training data used to build the multiple linear regression models with \( x \) consisted of 5 attribute values with \( y \) as the rate of anomaly. Then, with the Minitab tool, the multiple linear regression model was built as formulated in Eqs. (2), (3) and (4):

\[ y_H = 0.220 + 0.858 x_1 + 1.03 x_3 + 0.587 x_4 \]  

\[ y_M = 0.229 + 0.196 x_1 + 1.01 x_3 + 0.594 x_4 + 0.666 x_5 \]  

\[ y_L = 0.545 + 0.405 x_1 + 0.304 x_3 - 0.115 x_4 + 0.196 x_5 \]  

where \( y \) denotes the output of the MLR model.

2.2. Support vector regression

SVR is based on the same principle as SVM, with some small differences. The main difference is that it produces a continuous output instead of a discrete output corresponding to the real numbers.

in the regression problem. Epsilon needs to be set as a tolerance margin in SVM because it is difficult to predict continuous information with unlimited possibilities. In the regression analysis, the main idea is always to minimize the error considering the tolerance margin (Estelles-Lopez et al., 2017). In this experiment, the RBF kernel function can be expressed as in Eq. (5), where \( \|x_i - x_j\|^2 \) is the square Euclidean distance and \( \sigma \) is a free parameter:

\[
k(x_i, x_j) = \exp\left(-\frac{\|x_i - x_j\|^2}{2\sigma^2}\right)
\] (5)

2.3. Fuzzy regression

In previous studies, such as (Shapiro, 2005), fuzzy regression (FR) was used to predict the association of risk factors with work-related injuries. According to (Uejima and Asai, 1982), the general form of the model is as shown in Eq. (6).

\[
\bar{Y} = \bar{b}_0 + \bar{b}_1 x_1 + \bar{b}_2 x_2 + \bar{b}_3 x_3 + \bar{b}_4 x_4 + \bar{b}_5 x_5
\] (6)

where \( \bar{Y} \) is the fuzzy output, \( x_1 \) – \( x_5 \) are non fuzzy input vectors, \( B_1 \) – \( B_5 \) are independent variables, and \( B_0 \) is a dependent variable. The membership function (MF) \( \mu_a(x) \), as shown in Fig. 1, uses a trapezoidal membership function for better results in most of the cases. The selection criteria of \( a, b, c \) and \( d \) are used for rate of anomaly (ROA) membership.

Based on Fig. 1, \( \mu_a(x) \) is a mode. The basic idea of the fuzzy regression approach is to minimize the model's ambiguity. Two common methods for developing a fuzzy regression models are: (1) models in which the relationship between the variables are fuzzy; and (2) models in which the variables themselves are fuzzy (Sánchez and Gómez, 2004; Andrés-Sánchez, 2016; Bell and Heng, 1997; Pedregosa et al., 2011). Here, we focused on models in which the data are discrete and the relationships between the variables are uncertain.

In the experiment, the ROA values \( \bar{Y} \) consisted of High ROA \( \bar{Y}_H \), Medium ROA \( \bar{Y}_M \) and Low ROA \( \bar{Y}_L \), predicted by five predictors \( (x_1, x_2, \ldots, x_5) \). To build the fuzzy regression models, the method differs from multiple linear regression. The first step is to build the membership of the 5 attributes, i.e. Skip Sequence, Wrong Throughput Time (Min), Wrong Throughput Time (Max), Wrong Decision, Pattern and Rate of Anomaly. The next step is to divide the anomalies into low, medium and high anomalies to find the fuzzy rate of each criterion. Then multiple linear regression is used to obtain the equation for fuzzy low anomaly, fuzzy medium anomaly and fuzzy high anomaly for the training process. Equations (7), (8) and (9) are the resulting regression equations for fuzzy low anomaly, fuzzy medium anomaly, and fuzzy high anomaly, respectively. Thus, the FR model can be formulated as shown in Eq. (7), Eq. (8) and Eq. (9).
The fuzzy regression method proposed in this paper was evaluated by measuring its accuracy of anomaly detection. This research used sensitivity, specificity and accuracy as the metrics (Liu et al., 2013). Sensitivity measures how many positive anomaly instances were correctly identified, specificity measures how many negative anomaly instances were correctly identified, and accuracy measures the level of proximity of the measurement results with the actual anomaly values. The equations for calculating sensitivity, specificity and accuracy are Eq. (11), Eq. (12), Eq. (13). The confusion matrix is shown in Table 5. In Eq. (11), the variable True Positive stores the number of correctly identified positive anomaly instances and False Negative stores the number of incorrectly identified positive anomaly instances. Here, we did not consider false alarm performance. In Eq. (12), the variable True Negative stores the number of correctly identified negative anomaly instances.

### 2.4. The accuracy of detecting an anomaly

The fuzzy regression method proposed in this paper was evaluated by measuring its accuracy of anomaly detection. This research used sensitivity, specificity and accuracy as the metrics (Liu et al., 2013). Sensitivity measures how many positive anomaly instances were correctly identified, specificity measures how many negative anomaly instances were correctly identified, and accuracy measures the level of proximity of the measurement results with the actual anomaly values. The equations for calculating sensitivity, specificity and accuracy are Eq. (11), Eq. (12), Eq. (13). The confusion matrix is shown in Table 5. In Eq. (11), the variable True Positive stores the number of correctly identified positive anomaly instances and False Negative stores the number of incorrectly identified positive anomaly instances. Here, we did not consider false alarm performance. In Eq. (12), the variable True Negative stores the number of correctly identified negative anomaly instances.
and False Positive stores the number of incorrectly identified negative anomaly instances.

\[
\text{Sensitivity} = \frac{\text{True Positive (TP)}}{\text{True Positive (TP) + False Negative (FN)}}
\]  
\[\text{(11)}\]

\[
\text{Specificity} = \frac{\text{True Negative (TN)}}{\text{True Negative (TN) + False Positive (FP)}}
\]  
\[\text{(12)}\]

\[
\text{Accuracy} = \frac{\text{True Positive (TP) + True Negative (TN)}}{\text{True Positive (TP) + True Negative (TN) + False Positive (FP) + False Negative (FN)}}
\]  
\[\text{(13)}\]

3. Results

The proposed method consists of two steps. The first step is composing the control-flow patterns (CFP) with anomaly pattern rules. The second step is defining the attribute values of the anomalies.

Table 7

</tr>
</tbody>
</table>

3.1. Composing control flow patterns

For composing the anomaly patterns, several rules are proposed. The role model that is used in this research contains no_anomaly_patterns (a, c) and anomaly_patterns (a, c). The method of composing the anomaly patterns is shown in Table 6. The anomaly patterns are directly formed based on anomaly rules as shown in Table 7, which contains Sequence Patterns and Exclusive choice patterns as examples. Based on Fig. 3, the patterns are formed by considering the no_anomaly_patterns and anomaly_patterns rules. The process model was built with Yet Another Workflow Language (YAWL) (Huda et al., 2015; Rahmawati et al., 2017).

After composing the anomaly patterns, the control flow patterns are converted into string rules in a Java program to be used for detection of anomalies by finding wrong patterns in the event log. The method for detecting wrong patterns with anomaly pattern rules is shown in Fig. 4.

After getting the anomaly pattern rules, the degrees of the nodes are calculated, which are used for the parameters to detect wrong pattern anomalies using graph isomorphism (graph pattern matching). Wrong patterns can only be detected when the graphs are isomorphic. The requirement of graph isomorphism is fulfilled when the degrees of the nodes, and the number of arcs and nodes in both graphs are the same.

If these three requirements are met but the graphs are still not isomorphic, another additional factor is needed. A dependencies matrix is proposed to detect the similarity of two graphs by so-called graph pattern matching. Examples of the application of graph isomorphism with a dependencies matrix in a instance containing anomalies is shown in Fig. 5.
3.2. Defining attribute values of anomaly

The attribute values of the anomalies are obtained from the output values of the anomaly detection in the Java program. Pseudocode for detecting anomalies in a log of port container handling is shown in Table 8.

After the detection has been done automatically by the Java program, the output of the detection process contains values for each anomaly attribute. Table 9 shows the 5 anomaly attribute values.

4. Discussion

This research aimed to find the best algorithm for detecting anomalies, especially low anomalies. Previous methods treat instances of low anomaly as anomalies, but not all instances with low anomaly are anomalies. To deal with this issue, we propose a method for correctly detecting anomaly instances. We hypothesized that fuzzy regression is a good algorithm for detecting anomalies, especially low anomalies, because it can accommodate verbal expert judgments on rate of anomaly. We tested this hypothesis by measuring the specificity, sensitivity and accuracy of anomaly detection by the proposed method.

The proposed method has already been implemented and evaluated in a program in port container handling from December 2015 to March 2016. An expert in port container handling specified the thresholds to distinguish the No Anomaly, Low Anomaly, Medium Anomaly and High Anomaly classes.

In 65,000 port container handling data logs (December 2015-March 2016), the system found anomalies in 680 data logs and no anomalies in 64,320 data logs (see Table 2). Subsequently, 60% of the anomaly data were used as training data and 40% were used as testing data, as shown in Table 3. A screenshot of the program is shown in Fig. 5.

Fig. 5. Wrong pattern with dependencies matrix.

Please cite this article as: D. Rahmawati and R. Sarno, Anomaly detection using control flow pattern and fuzzy regression in port container handling, Journal of King Saud University – Computer and Information Sciences, https://doi.org/10.1016/j.jksuci.2018.12.004
gram for detecting Wrong Throughput Time (Min/Max) is shown in Fig. 6. Skip Sequence, Wrong Decision and Wrong Pattern are shown in Fig. 7.

The performance of the proposed method using MLR, SVR with RBF kernel and FR was evaluated to determine the best regression method for ROA prediction. Table 10 shows a visual comparison of MLR, SVR with RBF kernel and FR. Fig. 8 indicates that the ROA can be predicted well by MLR, despite some errors. The plot between the actual and the predicted ROA shows that the majority of predictions follow the line of equity \((y=x)\), with a margin of 0.30. However, some predictions of high anomalies differed greatly from the actual ROA. A high RMSE confirms that an instance belongs to the High Anomaly class (27.23). The values of \(R^2\) and adjusted \(R^2\) were only 0.3 and 0.2, respectively. They indicate that the MLR model could only correctly predict less than half of the actual ROA variance. The performance of SVR with RBF kernel is shown in Fig. 9. It showed better performance than MLR, especially for Low Anomaly and Medium Anomaly predictions. The overall RMSE value of 30% shows that it performed better than MLR but was less accurate than FR. FR, shown in Fig. 10, had the best performance against MLR and SVR with RBF kernel as shown by having the lowest RMSE and the largest portion of variance that could be correctly predicted by the model \((R^2 = 0.98 \text{ and } \text{adjusted } R^2 = 0.98)\).

Based on Fig. 10 and Table 10, fuzzy regression (FR) was used to classify the rate of anomaly after the output was decoded. Table 10 shows a performance comparison of MLR, SVR with RBF kernel and FR in predicting the rate of anomaly. The prefixes ‘true’ and ‘pred’ denote the actual and predicted values, respectively. The proposed fuzzy regression method showed the best performance against MLR and SVR with RBF kernel. It could recognize High Anomaly, Medium Anomaly, Low Anomaly and No Anomaly with an accuracy of 99%. SVR with RBF kernel recognized High Anomaly, Medium Anomaly, Low Anomaly and No Anomaly with an accuracy of 97%.

MLR and SVR with RBF kernel had difficulty detecting low anomalies. This is indicated by their low sensitivity, specificity and accuracy in low anomaly prediction. These results confirm that low anomalies are hard to recognize by ordinary classifiers. Fuzzy regression achieved the highest sensitivity, specificity and accuracy for the Low Anomaly class. The measurements of sensitivity, specificity and accuracy are presented in Table 11 and Figs. 11, 12 and 13, respectively. Fig. 11 presents a comparison of the sensitivity values of MLR, SVR with RBF kernel and FR. Fig. 12 shows a comparison of the specificity values of MLR, SVR with RBF kernel and FR, and Fig. 13 shows a comparison of the accuracy values of MLR, SVR with RBF kernel and FR.

5. Conclusions

In this study, a method for detecting low anomalies in container port handling that accommodates verbal expert judgments on rate of anomaly was developed. It was found that fuzzy regression performed better as part of the method compared to support vector regression with radial basis function kernel and multiple linear regression. Fuzzy regression achieved the highest sensitivity, specificity and accuracy for the Low Anomaly class. The result of the experiment confirmed that low anomalies are hard to recognize by ordinary classifiers, as proved by the sensitivity, specificity and accuracy values of the FR method, which were 96%, 97% and
99%, respectively. Further exploration of optimization to determine the membership function of interval type-2 fuzzy sets is needed. Future work also includes the effect of sigmoid and fuzzy type-2 membership functions to increase the specificity, specificity and accuracy of detecting low anomalies.
